Abstract: In this paper, we study long-term coastal flood risk of Lingang New City, Shanghai, considering 100- and 1000-year coastal flood return periods, local sea-level rise projections, and long-term ground subsidence projections. TanDEM-X satellite data acquired in 2012 were used to generate a high-resolution topography map, and multi-sensor InSAR displacement time-series were used to obtain ground deformation rates between 2007-2017. Both data sets were then used to project ground deformation rates for the 2030s and 2050s. A 2-D flood inundation model (FloodMap-Inertial) was employed to predict coastal flood inundation for both scenarios. The results suggest that the sea-level rise, along with land subsidence, could result in minor but non-linear impacts on coastal inundation over time. The flood risk will primarily be determined by future exposure and vulnerability of population and property in the floodplain. Although the flood risk estimates show some uncertainties, particularly for long-term predictions, the methodology presented here could be applied

to other coastal areas where sea level rise and land subsidence are evolving in the context of climate change and urbanization.

Keywords: Coastal flooding; Sea level rise; Land subsidence; InSAR; FloodMap

1. Introduction

The global mean sea-level has risen at an average rate of 1.6–1.9 mm/year during the 20th century (Hay et al. 2015), and the rate is projected to accelerate, with a total sea-level rise (SLR) of up to 2 m over the 21st century (Oppenheimer and Alley, 2016). However, the projections remain quite uncertain due to difficulties in estimating the rate of melting of glaciers and the melting of the Greenland and Antarctic ice sheets. The fifth Assessment Report (AR5) of the Intergovernmental Panel on Climate Change (IPCC) suggests higher SLR rates throughout this century based on recent ice-sheet observations (IPCC 2014), hence increased flooding risks for low-lying coastal zones. Coastal inundation risks under sea-level rise have been assessed and mapped extensively for many coastal regions, including, e.g., in Charlestown, RI, USA (Grilli et al. 2017), in the Italian coastal plains (Antonioli et al. 2017), in the coastal zones of Poland (Paprotny et al. 2017), in southeast Queensland, USA (Mills et al. 2016), in New York, USA (Orton et al. 2015, Lin and Shullman 2017), and in Shanghai in China (Wang et al. 2012).

Moreover, non-climate-related anthropogenic processes, such as ground subsidence due to groundwater extraction, extensive coastal settlements in lands reclaimed from the sea, and complex subsidence phenomena related to artificial sea walls, will exacerbate the flooding risk of coastal zones. There is a global consensus that land subsidence is a major problem in low-lying coastal zones around the world (Jelgersma 1996; Ericson et al. 2006; Syvitski et al. 2009; Teatini et al. 2011). Local sinking of land resulting from anthropogenic and natural processes, in combination with sea level rise caused by climate change, makes the situation worse for coastal settlements. A large number of studies has already stressed the

45 significance of relative SLR in increasing coastal flood frequency and intensity (Karegar et al. 2017; Little et al. 2015; Shi
46 et al. 2012; Cayan et al. 2008; Carminati et al. 2002). For example, with a relative SLR from 0.5 m to 1 m predicted by the
47 2080s, a 100-year flood is projected to occur 2 to 4 times more often for New York City (Horton et al. 2015).

48

49 Recent advances in InSAR techniques (Higgins, 2016; Mason et al., 2016; Massonnet and Feigl, 1998) and the advent of
50 simplified hydraulic models have enabled high resolution scenario-based flood modeling in the context of SLR and land
51 subsidence. Remotely sensed digital elevation models (DEMs) with varying resolutions have been widely applied for flood
52 modeling (Hinkel et al. 2014; Sampson et al. 2015; Domeneghetti, 2016). Although LiDAR DEMs have optimal resolution
53 and accuracy, they do not have global coverage and are not available over broad areas, particularly in developing countries.
54 Open source DEMs with global coverage, such as Shuttle Radar Topography Mission (SRTM) and Advanced Spaceborne
55 Thermal Emission and Reflection Radiometer Global Digital Elevation Model (ASTER GDEM), have demonstrated
56 remarkable usability for large-scale flood modeling (e.g. Syvitski et al. 2009; Sampson et al. 2015). However, the 90-m
57 SRTM and 30-m ASTER DEMs have significant limitations due to their coarse vertical accuracy (around 12-18 m) (Meyer
58 et al. 2011; Tachikawa et al. 2011; Yang et al. 2011). In recent years, data from the bistatic TanDEM-X satellite mission
59 have enabled the generation of DEMs with a horizontal resolution of 12 m and a vertical accuracy of 2-4 m with global
60 coverage (Krieger et al. 2007). Moreover, time-series Differential Synthetic Aperture Radar Interferometry (DInSAR) have
61 been developed to measure Earth's surface ground displacement over large areas with high spatial resolution, on the order
62 of meters, and with a temporal repetition time of 35 days (ERS and ENVISAT/ASAR sensors) and 6 days (Sentinel-1
63 sensors) (Berardino et al. 2002; Crosetto et al. 2016). Currently, with a growing number of SAR images collected by
64 different satellite missions with peculiar looking angles and operating wavelengths, a long-term (over ten years)
65 displacement time-series can be retrieved using DInSAR techniques (Samsonov 2012; Pepe et al. 2016 a, b). In addition,
66 simplified hydrodynamic models (e.g. LISFLOOD-FP, JFLOW, FloodMap) have been increasingly used for flood

modeling at different scales as they can capture the dominant physics of overland flood processes and take input topography in the format of a regular grid. They have been proven to perform as well as full 2-D models for the treatment of coastal flooding (utilizing an unstructured mesh to represent topography), but at a substantially reduced computational cost (Bates et al. 2005; Yin et al. 2016).

In this study, we used the Small Baseline Subset (SBAS) DInSAR technique to jointly analyze SAR data from different sensors together with a simplified hydrodynamic model (FloodMap, Yu and Lane 2006a, b; Yu and Coulthard, 2015) to investigate the evolving flood risk in a changing climate of Lingang New City in Shanghai, a recently-reclaimed coastal environment. The scenarios used in this paper can be defined as series of events including different flood return periods, sea level and subsidence projections, and future land use in Lingang New City. The main goals of this study are to (i) provide a full characterization of surface changes over time in the coastal delta environment, (ii) derive coastal submerged areas under combined SLR and land subsidence scenarios, and (iii) assess potential coastal flood impacts on a fast growing waterfront urban area. The remainder of this paper is organized as follows. Section 2 describes the study area, whereas Section 3 introduces materials and methods, including the DEM generation, land subsidence measurement, SLR projections, and coastal flood modeling. Section 4 presents the results and discussions. Conclusions and future research directions are provided in Section 5.

2. Study area

Lingang New City, a township at the east end of Shanghai, has been chosen as the study area, because it is highly vulnerable to coastal flooding and is affected by a significant land subsidence over the past decade (Wang et al. 2012). The study site is surrounded by the Yangtze River estuary, East China Sea and Hangzhou Bay (Fig. 1). It covers about 315 km² of the

89 southeast part of Pudong New Area with a flat and low-lying topography (on average about 4 m above the Wusong Datum).
90 According to China Sea Level Bulletin (2008, 2017), mean sea level in the area has been rising with an average rate of 3.8
91 mm/a during the past 30 years, and has been empirically estimated as up to 150 mm in the next 30 years. Lingang has been
92 historically experiencing variations in landscape due to changes in natural forcing and intensive human activities, such as
93 sediment deposition, erosion, sand excavation, dam construction and land reclamation (Yang et al. 2011). Human activities
94 have also greatly modified the coastal topography over the past decades. Since 2002, this area has been rapidly developed
95 to be a new sub-center for several functional zones (e.g., a Bonded Logistics Park). A large part of the region (133 km²),
96 representing approximately 42% of the total area, is sea-reclaimed land (Tian et al. 2016). The subsidence in reclamation
97 areas is dominated by soil compaction mechanisms, which are primarily responsible for vertical movements (Cai et al.
98 2008; Pepe et al. 2016a; Yu et al. 2017). Natural compaction of loose sediments and self-weight consolidation of dredger
99 fill, under intense urbanization, has caused significant land subsidence in this area.

100

101 In history, the area has been frequently affected by cyclonic storms, particularly during the flood season (June to
102 September). For example, during typhoon Winnie (1997), the storm surge peak coincided with an astronomical high tide
103 and resulted in the highest water level in record (5.66 m above Wusong Datum) at Luchaogang gauge station (Fig. 1), and
104 extensive flooding occurred in the coastal floodplain due to levee breach (Liu 2008). To protect against evolving coastal
105 floods, flood defense system in Lingang were constructed and reinforced several times over the past decades (Fan et al.
106 2017). In the 1970s, '85' (i.e., 8 m height and 5 m width levee crest) seawall has been built in response to an extreme
107 coastal flood event that occurred in August 1974. Since the end of the 20th century, higher standard seawall (i.e., around
108 10 m height) has been constructed to withstand a 200-year storm tide plus wave induced by 12-force winds.

3. Materials and methodology

3.1 DEM generation

The TanDEM-X mission has the innovative capability to simultaneously acquire two SAR satellite images (bistatic acquisition mode) with short along-track baselines, which enables us to derive high-resolution DEMs of the study area. With a pair of TanDEM-X images acquired on 04 November 2012, an up-to-date DEM of our study area, Lingang New City, has been generated using bistatic interferometry. The bistatic acquisition mode is characterized by illumination of an area on the ground by one transmitter and the simultaneous acquisition of the backscattered signals with two receivers. Compared to the monostatic acquisition mode, where only one image is acquired during every overflight of the satellite, temporal decorrelation and atmospheric disturbances, which severely affect the interferometric coherence, are significantly reduced in the TanDEM-X bistatic mode (Gruber et al. 2012). Moreover, since the SAR data pair is simultaneously imaged, the phase contribution due to ground deformation can be neglected. The interferometric phase is simplified in the bistatic

126 interferometry case as follows (Kubanek et al. 2015):

$$127 \quad \phi = \phi_{ref} + \phi_{topo} + \phi_{noise} \quad [1]$$

128 where ϕ_{ref} is the phase of the reference surface, i.e., WGS 84 (World Geodetic System 1984) ellipsoid; ϕ_{topo} is the
129 topographic phase; and ϕ_{noise} is the phase noise.

130 We generated the interferogram with the TanDEM-X pairs using the DORIS software packages (Kampes et al. 2003). The
131 interferometric phase can be expressed as follows (Kubanek et al. 2015):

$$132 \quad \phi = -\frac{2\pi}{\lambda} \Delta r \quad [2]$$

133 where Δr is the path length difference between the two (bistatic) SAR acquisitions and λ is the wavelength, which is 3.1
134 cm for TanDEM-X. Before phase unwrapping, i.e., before resolving the ambiguous phase, a Goldstein filter (Goldstein and
135 Werner, 1998) was applied to smooth the interferometric phase. The filtered interferogram was unwrapped using the
136 SNAPHU (Statistical-Cost Network-Flow Algorithm for Phase Unwrapping) algorithm (Chen and Zebker, 2001).
137 Subsequently, the path length difference of Eq. 2 was converted from phase-to-height (Bamler and Hartl 1998;
138 Franceschetti and Lanari 1999):

$$139 \quad h = -\frac{\lambda}{2\pi} \frac{R \sin \vartheta}{b_{\perp}} \psi \quad [3]$$

140 where $b_{\perp}$ is the orthogonal baseline of the InSAR pair, R is the sensor-to-target slant-range distance, ϑ is the sensor side-
141 looking angle, ψ represents the unwrapped phase relevant to the interferometric phase ϕ (compensated by the phase of
142 the reference plane), and h is the surface height.

143

144 The obtained topographic map h is then geocoded to geographic coordinates (WGS 84) using DORIS and gridded using
145 GMT (Wessel et al. 2013). A grid spacing of 6 m is selected for the DEM product and it is further resampled to 18 m
146 resolution to reduce computational costs. Fig 2 shows the generated Tandem-X DEM of the study area. The theoretical
147 accuracy and actual DEM performance of bistatic TanDEM-X InSAR were verified by Weigt et.al. (2012). Their

148 verification shows that for slopes less than 20%, the height error is predicted to be 1.7 m and 2.5 m for a height of ambiguity
 149 of 30 m and 45 m, respectively, for the global TanDEM-X data set. Kubanek et al. (2017) obtained a standard deviation of
 150 1.63 m for elevation differences of TanDEM-X DEMs that were generated to study the Tolbachik volcanic complex in
 151 Kamchatka, Russia, using the same methodology as used for DEM generation presented in this paper.

154

155 3.2 Long-term ground settlement measurement

156 Advanced time-series DInSAR algorithms can rapidly and regularly detect and measure ground deformation with a high
 157 accuracy and at different scales (Ferretti et al. 2001; Berardino et al. 2004; Hooper et al. 2012). DInSAR techniques have,
 158 among others, been applied for measuring and mapping ground deformation caused by over-pumping underground water
 159 (Gourmelen et al. 2007), tectonic movement (Fattahi et al. 2015), sediments consolidation of river deltas (Aly et al. 2012),
 160 and land reclamation (Zhao et al. 2015). Time-series DInSAR techniques have been proven being effective approaches for
 161 accurately measuring ground deformation (Casu et al. 2006; Zhao et al. 2014).

162

3.2.1 Multi-platform SAR displacement time-series

164

165 Three independent sets of SAR images, acquired by different satellites, were used to retrieve long-term ground
 166 displacement of Lingang New City. The former consists of 35 ENVISAT ASAR (ENV) images, acquired with ascending
 167 passes from February 26, 2007 to September 13, 2010. The second SAR set is composed of 61 COSMO-SkyMed (CSK)
 168 images, which were collected with descending passes from December 7, 2013 to March 18, 2016. The third set was
 169 collected by the Sentinel-1A (S1A) satellite with ascending passes from February 26, 2015 to April 4, 2017. All available
 170 SAR images were processed through the well-known Small BASeline Subset (SBAS) multi-temporal DInSAR technique,
 171 which is outlined in the next subsection.

172

173

174 Figure 3 Distribution of the available ENVISAT ASAR, COSMO-SkyMed, and Sentinel-1A SAR data in the temporal-

perpendicular baseline plane, as depicted in a), b), and c) respectively. The master images of ENVISAT ASAR, COSMO-SkyMed, and Sentinel-1A SAR data are represented by red diamonds.

3.2.2 Small Baseline technique

Small Baseline (SB) techniques are a class of advanced time-series DInSAR methods (Mora et al. 2003; Usai 2003; Berardino et al. 2002). In particular, the SBAS algorithm (Berardino et al. 2002, Lanari et al. 2007) is one of the well-known and highly used SB techniques. This algorithm is based on selecting a set of small temporal and perpendicular baseline interferograms, thus mitigating decorrelation phenomena, and allows the generation of mean deformation velocity maps and relevant displacement time-series for each coherent point. Fig. 3 (a)-(c) show the distribution of the three groups of SAR images used in this study in the temporal/perpendicular baseline plane. The small baseline interferometric SAR data pairs might be arranged in a few subsets. In order to generate a unique displacement time-series, the phase ambiguities of the differential SAR interferograms are preliminarily resolved, i.e., unwrapped (Costantini and Rosen, 1999, Pepe and Lanari 2006) and subsequently combined using the singular value decomposition (SVD) method. The residual topographic and atmospheric phase artifacts are also estimated and filtered out. The DInSAR products, i.e., the mean deformation velocity maps and the relevant displacement time-series, are finally geocoded to a common spatial grid. Interested readers can find a detailed description of the SBAS approach and the processing chain in Berardino et al. (2002).

3.2.3 Multi-platform time-series DInSAR

After the SBAS processing of the independent SAR datasets, the unique deformation time-series spanning the acquisition times of the overall SAR datasets is, however, still unknown. Indeed, it should be noted that the deformation time-series

are relative to the first SAR acquisition time of each independent dataset. In order to combine the deformation time-series obtained by multi-platforms, we need to determine the multi-platform deformation time-series relative to one global reference time. A methodology has been developed by Pepe et al. (2016a) to combine two time-gapped deformation time-series obtained by ENVISAT ASAR and COSMO-SkyMed SAR datasets. To this aim, the DInSAR-derived line-of-sight (LOS) deformation time-series was first independently projected into vertical deformation time-series by assuming the horizontal (east-west) deformation is negligible. Then, an external geotechnical centrifuge model (Yang 2008), representing a complete time-settlement curve in reclaimed areas of Shanghai, was exploited and fitted to data to jointly estimate the unique deformation time-series over the entire time period between 26 February 2007 and 18 March 2016 (Zhao et al. 2015, Pepe et al. 2016a). Note that deformation due to reclamation can be distinguished in the primary consolidation phase, which takes place immediately after the completion of the reclamation process, and in the secondary compression stage of the alluvial deposit creep of the reclamation fill (Yang 2008), which can last several years after the completion of the reclamation procedures. The used laboratory centrifuge model permits to analyze the temporal evolution of the (vertical) ground displacement due to the self-weight consolidation (including both the primary and secondary compression stages) of the ocean-reclaimed lands. The used model is expressed as follows (Zhao et al. 2015):

$$s(t) = S_m \frac{(t - \delta)^\mu}{k^\mu + (t - \delta)^\mu} \quad [4]$$

where t represents the consolidation time, S_m is the asymptotic (cumulative) deformation assumed at infinite time (i.e., when the soil consolidation process is ended), δ accounts for the (variable) starting time of the reclamation process, and k and μ are model parameters that influence the shape and curvature of the time-dependent model.

First, the combined ENV+CSK deformation time-series were determined, for each radar pixel, by finding the best-fit between the geotechnical model and the multi-platform deformation time-series. The nonlinear optimization problem was solved efficiently through the (iterative) Levenberg–Marquadt least squares (LS) minimization technique. Subsequently,

219 the Sentinel-1A displacement time-series was independently generated by applying the SBAS technique, converted into
 220 (vertical) displacement time-series and finally combined to the previously obtained ENV+CSK displacement time-series.
 221 This procedure is repeated for each coherent radar pixel of the investigated scene. Due to the time overlap between the
 222 combined ENV+CSK and S1A subsets, the time-series were linked using SVD by extending what was originally proposed
 223 in Berardino et al. (2002). Finally, the long-term deformation time-series with a time-span of approximately 10 years (from
 224 2007 to 2018) were obtained. Fig. 4 (a)-(b) show the maps of the asymptotical ground deformation, namely the term of the
 225 best-fit model between the combined ENV+CSK and ENV+CSK+S1A displacement time-series and the model,
 226 respectively. As evident, there is a good agreement between the two maps, thus indicating that the Levenberg-Marquadt
 227 LS optimization procedure is robust to data. Additional remarks and the discussion of the DInSAR results are presented in
 228 Section 4.3.

229

230

231 Figure 4. Maps of asymptotic ground deformation from Nov 2012 to the end time of the consolidation phase derived with
 232 the best fit model constrained by ENV+CSK (left) and ENV+CSK+S1A (right)

233

234 Additionally, some measurements of the displacement affecting the seawalls, as gathered from leveling measurement

235 campaigns in 2009 (Chen et al. 2016), were also available to us. Figure 5 (a)-(b) shows the vertical mean deformation rate
 236 of the seawalls as seen from the leveling and the SBAS measurements (Zhao et al. 2015). It should be noted that we show
 237 the distribution of high-coherent pixels seen by ENVISAT in Figure 5(b) because the available corresponding leveling
 238 measurements span approximately the same time period of the ENVISAT acquisitions. The cross comparison between
 239 leveling and SBAS data shows a good agreement. Finally, starting from the retrieved parameters and the time vector t of
 240 the best-fit model of Equation (3) (see Zhao et al., 2015 for additional information), the expected cumulative deformations
 241 (calculated with respect to 26 February 2007) for January 1st of 2030 and 2050, respectively, were predicted.

242

Figure 6 Accumulated ground deformation projections for 2030s (a) and 2050s (b) in Lingang New City

3.3 Sea level rise projections

Sea level change shows significant local or regional differences due to both climate change and non-climatic factors such as land processes, ocean circulation and atmospheric pressure (Cooper et al. 2008; Hallegatte et al. 2011). Recently, Kopp et al. (2014) presented a global set of probabilistic local sea-level projections which quantified SLR contributions from global processes (e.g., the thermal expansion of ocean water) to local factors (e.g., glacial isostatic adjustment). It has been widely used for flood risk analysis (e.g., Lin and Shullman 2017). The dataset includes 17 station-based SLR projections in China's coastal areas, among which one station (Lvsi) located at the Yangtze River Estuary. We use the SLR projection of this station in the present study. Compared to the aforementioned statistical SLR studies (e.g. Li et al. 1998), Kopp et al. (2014) show a significant higher rise in local sea level. To account for plausible extreme conditions, we adopted the high-end estimates (i.e., 95th percentiles of model-based distributions) of Kopp's SLR projection at Lvsi for the 2030s (0.31 m) and 2050s (0.61 m), the two future time frames considered in this study.

3.4 Coastal flood modeling

In order to derive coastal flood inundation, FloodMap-Inertial, a well-established 2D hydrodynamic model was employed in this study (Yu and Lane 2011). This model, as well as an earlier diffusion-based version of it (Yu and Lane 2006a, b), has been extensively applied in a number of different environments such as coastal regions, urban areas and basins (e.g., Casas et al. 2010; Yin et al. 2013, 2016a, 2016b). It is raster-based and solves the inertial form of the 2D shallow water equations. Flood routing takes the same form as the inertial algorithm of Bates et al. (2010), but with a slightly different

method to calculate the time steps. The details of the model are described in Yu and Lane (2011). Therefore, we only focus on the major features of the model. Neglecting the convective acceleration term in the Saint-Venant equation, the momentum equation becomes:

$$\frac{\partial q}{\partial t} + \frac{gh\partial(h+z)}{\partial x} + \frac{gn^2q^2}{R^{4/3}h} = 0 \quad [5]$$

where q is the flow per unit width, g is the acceleration due to gravity, R is the hydraulic radius, z is the bed elevation, h is the water depth, and n is the Manning's roughness coefficient. R can be approximated with h for wide and shallow flows. Discretizing the equation with respect to time produces:

$$\frac{q_{t+\Delta t} - q_t}{\Delta t} + \frac{gh_t\partial(h+z)}{\partial x} + \frac{gn^2q_t^2}{h_t^{7/3}} = 0 \quad [6]$$

where one of the q_t in the friction term can be replaced by $q_{t+\Delta t}$, resulting in the explicit expression of the flow at the next time step:

$$q_{t+\Delta t} = \frac{q_t - gh_t\Delta t(\frac{\Delta(h+z)}{\Delta x})}{(1 + gh_t\Delta t n^2 q_t / h_t^{10/3})} \quad [7]$$

The flow in the x and y directions are decoupled and take the same form. Discharge is evaluated at cell edges and depth at the cell center.

To apply FloodMap for coastal flood simulation, time-series of water level along the land-sea boundary are used as input to drive 2D inland flow routing. The shape of the stage hydrograph at the boundary section was derived from the hourly recorded water level available at Luchaogang gauge station during Typhoon Winnie. Assuming tidal cycles remain constant, time-series of the 100- and 1000-year design flood heights above Wusong Datum were generated by scaling Typhoon Winnie's surge heights. To balance the accuracy and computational costs, 24-hour stage hydrographs, including two rising phases and two falling limbs, were applied to simulate the coastal flood processes. To account for the effect of SLR, the projected SLRs were linearly added to the state of 2012 to create the flood scenarios for the 2030s and 2050s. Due to lack

285 of available verification materials (e.g., high watermarks and observed flood extent) in the study area, an empirically-based,
286 relatively low floodplain roughness value of 0.03 which corresponds to the n Manning roughness coefficient, was used in
287 the simulations to represent the effect of tidal-flat area and open land on coastal flood routing.

288

289 Given the high design standard of seawalls built along the coastline of Shanghai, coastal flooding was not expected to
290 affect the region significantly, assuming seawalls are intact during storm surge events. Comparison of seawall heights (both
291 with and without land deformation) and projected peak surge values suggest that future storm surge events of up to 1000-
292 year magnitude would only affect the region marginally. However, coastal flooding did occur historically (e.g., 1997
293 Typhoon Winnie) along this part of the coastline, due to seawall breaching. Therefore, we generated breaching scenarios
294 based on the actual conditions of the seawalls obtained from a field survey and the observed & projected deformation rates
295 (Fig. 5 and 6). According to ‘Code for design of sea dike project (GB/T 51015-2014)’ in China, sections with subsidence
296 rates higher than 50 mm/a, which were in particular vulnerable to burst under the combined effect of wave and storm surge,
297 were removed from the seawall system in the simulation.

298

299 **3.5 Flood sensitivity analysis**

300

301 Due to the scenario-based nature of this study, we used a theoretically most appropriate roughness value (i.e., 0.03) in flood
302 modeling. However, in the context of flood inundation modeling for historical events, floodplain friction was found to
303 introduce bias into the modeling results. Therefore, model sensitivity to roughness parameterization was evaluated with
304 FloodMap by varying the Manning's n values (between 0.01 and 0.1 at a 0.01 interval).

305

306 In order to detect the spatio-temporal changes in flood inundation, two metrics (i.e., Fit statistic (F) and Root Mean Square

Deviation (RMSD)) were used to quantify the degree of matching and variation between model predictions respectively. In each case, the $n=0.01$ simulation was used as the reference and both measures are calculated against this reference. F is widely used for evaluating the goodness of agreement between predicted flood extent and the reference (Bates and De Roo, 2000; Horritt and Bates, 2001; Yu and Lane, 2006). It varies between 1 for a perfect fit and 0 when no overlap exists. It can be calculated as follows:

$$F = \frac{A_o}{A_r + A_s - A_o}$$

where A_r is the referenced wet areas, A_s is the predicted wet areas, and A_o is the overlap of A_r and A_s .

The RMSD is particularly suitable for evaluating the overall agreement/discrepancy of water depth between two paired results on a cell-by-cell basis (Yu and Lane, 2011; Yin et al. 2016). It can be defined as follows:

$$RMSD = \sqrt{\frac{\sum_{i=0}^n (d_i^s - d_i^r)^2}{n}}$$

where d_i^s and d_i^r are the predicted and referenced water levels (or depths) respectively, i is the index of the wet cells and n is the total number of wet cells in the prediction and observation.

4. Results and discussions

4.1 Coastal inundation mapping

Predicted maximum inundation depths for 100-year and 1000-year coastal flood scenarios due to hypothetical levee breaches for the present (i.e., 2012), the 2030s and the 2050s are shown in Fig. 7 and the maximum flooded areas are summarized in Table 1. The mean maximum flood depth in the table represents the average value of maximum flood depths in all grids during the flood model run. Comparison of the derived inundation maps leads to two important findings. First,

329 similar inundation pattern are generally observed for both simulations (one in 100- and 1000-year return periods) in the
 330 study area, but with different flood depths. This can be largely attributed to the topographic confinement of the coastal
 331 floodplain. The levee-breach flow would be blocked by the previous seawall (Fan et al. 2017), and thus the water would
 332 be mostly confined within the coastal flat and low-lying areas where land was only recently reclaimed in the past decade
 333 (Zou et al. 2007). In addition, Dishui Lake which has a total area of 5.56 km² and a storage of 16.2 million m³, also shows
 334 a significant impact on the detention and storage of the storm water, restricting further inland propagation of coastal flood
 335 waves.

336

337 Table 1 The areas (km² and percentage of computation domain) and depths subject to different levee-breach coastal flood
 338 scenarios under sea level rise and land subsidence projections for Lingang New City, Shanghai

339

Time	High-end sea level rise (m)	Mean land subsidence (m)	Maximum flood areas (km ²) and percentage (%)		Mean maximum flood depths (m)	
			100y flood	1000y flood	100y flood	1000y flood
2012	/	/	32.79 (13.14%)	34.30 (13.74%)	1.33	1.45
2030	0.31	0.13	34.72 (13.91%)	36.37 (14.57%)	1.44	1.59
2050	0.61	0.28	37.76 (15.13%)	42.18 (16.90%)	1.56	1.76

340

341 Second, our results show that rapid sea-level rise combined with extensive land subsidence generally leads to minor but
 342 non-linear impacts on coastal inundation over time in our study area. For example, when the 0.44 m and 0.89 m rise in the
 343 relative sea level (i.e. the sum of SLR and subsidence projections) for the 2030s and the 2050s are considered, a 6% and
 344 15% increase in predicted maximum inundation area can be observed for future 100-year flood events. Similarly, compared
 345 to 2012, the mean water depths are projected to rise 0.11 m (8%) by 2030 and 0.23 m (17%) by 2050, respectively. In
 346 contrast, the impact of the projected relative sea level rise appears to be more pronounced for 1000-year flood events,
 347 where the total flood area is expected to increase by 23% by 2050; the maximum water depth will rise by 21%. Although
 348 mean land subsidence only makes up around 30% of the relative sea level rise, coastal flooding response is also controlled

349 by a non-uniform pattern of subsidence. It was found that rapid subsidence would further accentuate inundation extent and
350 depth in the reclamation area, making it more vulnerable to coastal flooding.

351

352 In order to detect the temporal changes of coastal flood dynamics, the time evolution of predicted inundation areas for all
353 scenarios are presented in Fig. 8. The curves mostly coincide during the initial wetting phase (up to 7 h), suggesting that
354 levee-breach water flow extends progressively overland before and after the first flood peak, due to the mild relief and flat
355 topography of the coastal floodplain. After the rapid inland intrusion in each simulation, the inundated area increases only
356 slightly with a much higher stage during the second rising phase, indicating that further widespread expansion of coastal
357 flooding is limited due to strong resistance from surface obstruction. This finding also confirms the topographic
358 confinement of the coastal floodplain, which we identified in Fig. 2. Moreover, as shown in Fig. 8, the general pattern of
359 simulated time series revealed that the temporal characteristics of the inundated area is not strictly synchronous with the
360 timing of the tidal cycle. In most cases, the flood extent continues to increase even as the stage recedes, because the
361 floodwater level greatly overwhelmed low-lying waterfront ground. Another important finding is that the relative SLR
362 provides an elevated base for a storm flood to build upon and SLR and land subsidence may lead to more pronounced
363 impact on coastal inundation during the falling limbs of tidal hydrograph (Yin et al. 2013).

Figure 7 Potential levee-breach 100-year and 1000-year coastal flood inundation scenarios modeled with up-to-date and high resolution DEM and long-term DInSAR derived ground deformation time series for Lingang New City of Shanghai in 2012, the 2030s and the 2050s

Figure 8 Time series of inundation extents and water levels with 100-year and 1000-year flood return periods in 2012, 2030s and 2050s for Lingang New City of Shanghai

372

373 **4.2 Coastal flood impacts**

374

375 Coastal floodings, as derived by our models, will affect areas of current and future land use, where data are officially
376 provided by the Shanghai Institute of Surveying and Mapping (Fig. 9). An immediate finding is that although the Lingang
377 area has experienced rapid urbanization during the last decade, wetlands and bare lands mainly dominate the floodplain
378 and therefore flood impacts have a minor effect on the coastal communities. At present, considerable personal injury and
379 property damage are unlikely to occur in this area. However, according to the land use planning for Lingang New City, the
380 process of urbanization and floodplain development is expected to accelerate in the near future. According to the Lingang
381 New City Plan, the total population is expected to rise from about 50-100 thousand today to 1-1.5 million in the next
382 decades. Thus rapid expansion in human settlements is expected to occupy the waterfront areas around Dishui Lake. If
383 long term subsidence combined with strong storm tide causes the emergence of levee breach, extensive coastal flood
384 inundation would occur throughout the area in the 2030s and 2050s, leading to significant casualties and losses. In addition,
385 future flood risk could also be significant in the northern part of the coastal floodplain, where comprehensive industrial,
386 research & development, service, and residential areas may be constructed in the future. Compared to the direct impacts,
387 possible indirect consequences, such as interruption of public services or negative influences on industrial production and
388 living, would be more pronounced. The indirect impacts may last a few days to even a few months after an extreme event
389 (Yin et al. 2016b).

Figure 9 Land uses/planning fall within the predicted inundation areas (highlight) at current and future states: a) 100y flood in 2012; b) 1000y flood in 2012; c) 100y flood in 2050s; and d) 1000y flood in 2050s

4.3 Uncertainty and limitations

Uncertainties are inherent in a changing environment. In our study, the long term flood-risk mappings could be highly uncertain due to the assumptions and limitations associated with data and methods used here. First, in terms of SLR projections, the response of the Greenland and the West Antarctic ice sheets to future global warming is the largest long-

term source of uncertainty. Although the likelihood of the ice sheet collapse within the coming century has been described as extremely low (black swan, i.e., an event or occurrence that deviates beyond what is normally expected of a situation and is extremely difficult to predict), a partial or complete collapse of the Western Antarctic Ice Sheet will cause the global mean sea level to rise up to 4 m (Bentley, 1998; Vaughan and Spouge, 2002; Pfeffer et al. 2008; Bamber et al. 2009; Ritz et al. 2015; DeConto and Pollard, 2016). Second, coastal storminess is projected to change with climate change (Lin et al. 2012, 2015). Future frequency of extreme storms is very likely to increase until 2100 (IPCC 2012). It is yet unclear how a changing storminess, in combination with SLR, will affect the frequency and intensity of coastal flooding in Shanghai. Third, the flood modeling conducted in this study is based upon an arbitrary assumption that levee breaches will occur in the locations/sections with an observed subsidence rate higher than 50 mm/a. There are certain limitations and errors associated with such hypothesis, as the mechanism of seawall failure is determined by different triggering factors, including material and structure of the seawall, geologic conditions, and hydrodynamics (e.g., waves). The impacts of land subsidence on the stability of seawall and the threshold of levee breaches should be explicitly tested and verified.

411

Another source of uncertainty arises from the long-term (over twenty years) ground deformation projections. Although the long-term vertical deformation is predicted with best-fit models, which are obtained using the time-dependency laboratory models constrained by multi-platform DInSAR measurements (Pepe et al. 2015), uncertainties in estimating the asymptotic values of deformation might depend on the temporal length of the available, constrained DInSAR time-series. The longer the DInSAR displacement time-series the more accurate is the fit between the DInSAR data and the foreseen models. To get an idea of such uncertainties, we calculated the asymptotic ground deformation values of each high coherent point from November 2012 until the end of the consolidation phases with the best-fit models constrained by the combined ENV+CSK and ENV+CSK+S1A deformation time-series. As anticipated in Section 3.2.3, Fig. 4 shows the maps of asymptotic ground deformation, indicating that the asymptotic values of deformation agree well with the best fit models derived by ENV+CSK

421 and ENV+CSK+S1A in most of the study areas. Most of the points with different asymptotic values (see Equation (3)) of
 422 deformation are located along the seawall and the east of Dishui Lake. In particular, Table 2 presents the asymptotic values
 423 of deformation at four points labeled as a, b, c, d in Fig. 4. According to the quantity values of uncertainties in ground
 424 deformation prediction, the observed deviation is acceptable for the long-term flood-risk mapping. It is worth remarking
 425 that our predictions are based on the analysis of only ten years of data, and are relevant to a very dynamical coastal area
 426 that is highly affected by human activities. More lands are expected to be reclaimed along the current coastline in future
 427 decades. Accordingly, continuous DInSAR measurements are necessary for monitoring and progressively measuring the
 428 changes and for updating the projections.

429

430 Table 2 Total cumulative deformation values and end time values of consolidation phases between the best-fit models
 431 retrieved by using the combined ENV-CSK time series and the ones extracted from the combined ENV-CSK-S1A time
 432 series. The end of consolidation phase has been considered, for each radar pixel, as the time in correspondence to which
 433 the expected surface displacement rate is smaller than 0.5 mm/year.

		Best fit model derived with ENV+CSK	Best fit model derived with ENV+CSK+S1A
a	End time of consolidation	2015	2015
	Asymptotic values of ground subsidence (mm)	2	2
b	End time of consolidation	2030	2031
	Asymptotic values of ground subsidence (mm)	62	60
c	End time of consolidation	2035	2035
	Asymptotic values of ground subsidence (mm)	93	109
d	End time of consolidation	2060	2057
	Asymptotic values of ground subsidence (mm)	118	109

434

435 Flood model uncertainties have been addressed and time-series of F-statistic and RMSD for each simulation are shown in
 436 Fig. 10. The results show significant variations in the spatio-temporal pattern between individual simulations and the
 437 $n=0.01$ reference, suggesting the model's strong sensitivity to floodplain roughness. Another finding is that with higher

438 Manning's n values, the differences in inundation area and depth becomes less pronounced throughout the simulations,
 439 especially in terms of RMSD. The sensitivity of the RMSD is progressively magnified as the flood magnitude increases
 440 over time. On the contrary, higher magnitude flood events (e.g., 1000-year floods) appear to be less sensitive to roughness
 441 due to the lateral confinement of the floodplain. This observation reveals that coastal flood inundation is highly uncertain
 442 in the rapidly developing area, particularly for long-term predictions.

444
 445 Figure 10 Time series of F statistic, and depth RMSD for current 100- (left column) and 1000-year (right column) flood
 446 simulations with different Manning's n values

448 5. Conclusions

449
 450 This paper demonstrates a novel approach to evaluate evolving flood hazard in the context of sea level rise and land

451 subsidence for Lingang New City in Shanghai through an integration of 2D numerical flood modeling and InSAR
452 techniques. A number of conclusions can be drawn from the results obtained in this study. First, even with rapid sea level
453 rise and extensive land subsidence in the future, coastal flood inundation due to potential levee breach is predicted to occur
454 mostly in the waterfront low-lying areas, because of topographic confinement in the floodplain and blockage of previous
455 seawalls. Second, flood impacts in this area are expected to be minor due to a very low exposure of the population and
456 property at present, but future flood risk could be significantly higher as rapid urbanization and large-scale coastal
457 development have been planned in the floodplain. Finally, limitations, biases and even errors in local SLR projections,
458 storm climatology projections, levee breach estimations, ground deformation predictions, and coastal flood modeling may
459 have induced substantial uncertainties in the final estimates.

460

461 The methodology proposed here could be applied to other coastal communities facing significant SLR, subsidence and
462 flooding challenges. It may contribute to a better understanding of the long-term coastal flood hazard at local scale, and
463 thus help to develop sustainable flood risk management in coastal communities. However, to derive more robust
464 conclusions, further research should include: (1) analyzing the mechanisms and probabilities of seawall failure to provide
465 a more complete picture of levee breach; (2) evaluating the impacts of extreme SLR scenarios (e.g., collapse of the West
466 Antarctic Ice Sheet) and projected storminess due to climate change on coastal flooding; (3) coupling soil compaction
467 mechanics with time-series InSAR measurements to generate more reliable long-term ground deformation predictions; (4)
468 incorporating the ‘crowd sourced’ data and/or Unmanned Aerial Vehicle (UAV) remote sensing maps into flood model
469 calibration and validation, and (5) conducting quantitative assessment of coastal flood risk as well as cost-benefit analysis
470 of adaptation measures to support decision making with respect to financial investment. Finally, great efforts are required
471 to improve the accuracies in the datasets, models and future scenarios applied to coastal flood risk analysis.
