and	Children tend to resemble their parents in stature. Ady proportions, body composition, and rate of development. It may be assumed that barring the action of obvious environmental influences on growth (such as chemic illness or long-term malnutrition) these resemblances reflect the influence of genes that parents contribute
Roland Hauspie	to their biological outspring. A study published by rrow free and Lhorska (1969), based on a sample of 81 boys and 78 girls, is an example of this view. The subjects, all from Prague, were measured annually from birth to π = 20 years. The Prece-Baines growth curve was fit to the longitudinal data of π sch subject. From these
Laboratory of Anthropogenetics. Free Caucestic Balaseds, Beiguini	fitted curves for all the boys and girls, the three tallest, t^{-1} three shortest, the three slowest maturing, and the three fastest maturing of each s^{-1} were selected. None of these extreme cases was known to have any major chronic t^{-1} acute diseases. Neither the subject's history of common childhood diseases, nor the occupation of the fathers
	had an effect, positive or negative, on growth and development. In contrast, the mid- parent height did predict the adult stature of offspring. Mid-parent height is the average of the stature of the mother and the father. Inspection of the Preece-Baines
7001	curves showed that tall or short stature at age 20 could be predicted from stature at age four years. The positive impact of mid-parent stature or offspring growth and the predictability of adult height from stature at age four are $prima$ facta evidence for the role of heredity. Moreover, these findings attest to the party establishment of
	individual patterns of growth and their stability over time Other well-known research strategies are used to demonstrate the genetic determination of human growth. These strategies include the study of monozygotic
KLUWER ACADEMIC PUBLISHERS DOBDRECHT BOSTON - LONDON	and drzygouc twins, correlations in growin between plotey cut relatives ynotherwins, and the effects of genetic abnormalities on growth (reviewed in Bogin 1999). Studies such as these lend support to the concept of a "genetic potential" for body size, body composition and body proportions. The term "genetic potential" usually means that every human being has a genetically determined upper limited adult stature, the ratio

of leg "ength to softing-height, and other anthropometric dimensions. It is further assumed that an individual may achieve this "genetic potential" if the environment is free of mouts that delay or retard growth.

constitution of the fertilised egg" (Roche and Boell 1999). The quoted material is The origin of the idea of "genetic potential" in human development may be found Experimental support for this hypothesis came only in 1759 with the research of the German anatomist Kaspar Friedrich Wolff. He was able to show that the development of the organs of the chick in the egg did indeed develop from undifferentiated cells and tissues. Further research into embryology during the 19th century came to view prenatal development as largely fixed, or predetermined, in With the rediscovery of Mendel's principles of heredity in 1900, the mainstream view within developmental biology was that. "the basic potential nature and organisation of the structures of the organism are determined by the genetic from a popular electronic encyclopaedia. Note that the authors of this quote link the operates. This is one more example of the way in which the concept of in the sheary of epigenesis. In 1651 the English physician and anatomist William Harvey hypothesised that the specialised tissues, organs, and structures of the individual develop from unspecialised and undifferentiated cells in the ovum. words potential nature." "determined," and "genetic" to describe how developmental genetic potential" is ingrained in scientific and popular literature. biology nature.

Some scholars extend the concept of "genetic potential" from the individual to populations. Body-proportion differences between populations and ethnic groups are well known, and are often used to exemplify the concept of "genetic potential." Norgan (1998), for example states that, "The largest differences between ethnic groups, when all are growing up in good environments, are those of shape rather than size." Eveleth and Tanner (1990, p. 186) state. "These differences are certainly genetic in origin...." Both Norgan and Eveleth and Tanner (1990, p. 186) state. "These differences are certainly with a good deal of compelling data from growth research conducted on diverse humar populations. The data are, however, circumstantial as no genetic basis for the determination of human body proportions.

In Juddition to the use of circumstantial data to support the belief in a genetic determination of body proportions, several authors use a series of somatotype-like photographs of men of European or African origin. One version of these photographs, from the *Cambridge Eucyclopedia of Human Growth and Development* (1998, p. 360), is reproduced here as Figure 1. The caption for this version of the figure reads. "Comparison of European and African physiques, showing the relatively longer legs of Africans." The implication of this statement, and the accompanying article on body proportions, is that population differences in body shape are genetically determined. Note that the photographs of each man are reduced or enlarged in size so that all of the men have the same sitting height, as this makes the differences in leg length more clear.

÷ E

Figure 1. Comparison of European and Mercan Olympic 20 Fire physiques showing the relatively longer legs of Africans. In each 17 the four compares in the European athlete on the left. This figure was restinging 1 from a phonens whith the Cambridge Europedia of Human Growth and Development (Ulijas 1998, p. 360). Profession Tanner supplied the original photors 24.

The photographs were originally published in Tanner (1964), and are of Olympic athletes. Olympic athletes are a highly selected group of people. The body shape of Olympic athletes, including the ratio of leg length to sitting height, is strongly correlated with the type of sport performed. Moreover, Olympic athletes constitute only a very small segment of humanity, far smaller in number than would be required for reliable and accurate statistical analysis. Olympic athletes, then, are in no way representative of the general population in terms of biology or behaviour. Yet, a version of the original photographs has been reprinted in several textbooks, including both editions of Eveleth and Tanner's *Worldwide Variation in Human Growth* (1976, 1990), and is used to demonstrate genetic differences in growth potential between human populations.

The concept of "genetic potentials" in growth and body shape of human populations is well entrenched in the field of human growth research. Some scholars take the concept of "genetic potentials" as a given and use it without definition or justification from research, that is, without reference to the scientific literature. Interested readers may peruse recent issues of journals dealing with human biology, physical anthropology. paediatric medicine, and related fields, where they will find the concept of "genetic potential" used in this way.

The problem with this casual usage is that the assumption upon which it is based is not true. Existing research shows that adult stature, body proportions, and body composition are highly plastic. One of the clearest examples of the plasticity of human body proportions comes from Tanner et al.'s (1982) studies of relative lag length of Japanese children. In 1957 the relative leg length of adult Japanese was significantly less than that of Northern Europeans, and it was assumed that this difference was due mostly to genes. By 1977 the two ethnic groups had become virtually identical in shape. This invalidated the genetic explanation, which was replaced by an explanation favouring improvements in the physical and social environment of Japan. Research conducted in China (Zhang and Huang 1988), Argentina (Bolzan et al. 1993), Poland (Wolanski 1979), and Mexico (Gurri and discussed below). In these studies boys and girls of identical ethnicity and genetic Dickinson 1990, Wolanski et al. 1993, Wolanski 1995, Siniarska 1995) shows that the development of body proportions during the growing years is exquisitely sensitive to the quality of the local environment (reviewed in Bogin 1999 and background are compared, and children from lower SES families are significantly shorter in leg length than children of higher SES families.

In this article we re-examine the existing literature to see to what extent ethnic and population differences in body-proportions which are assumed to be of a genetic nature are, in fact, better explained by environmental plasticity in growth. We also present the findings of a new study of body proportion change in the children of Guatemalan immigrants now living in the United States. Finally, we make use of experimental findings on the determinants of fluctuating asymmetry in insects to develop an ecological model of body-proportion development.

WORLD-WIDE VARIATION IN HUMAN BODY PROPORTIONS - A NEW ANALYSIS

The first and second editions of the book *Worldwide Variation in Human Growth* (Eveleth and Tanner 1976, 1990) provide the most comprehensive compendia of

GENETICS OF BODY PROPORT 14S

human growth studies. The authors present data for relation several measures of hold proportions. Here we re-analyse the data for relation sitting height, which is calculated as [(sitting height/stature) × 100]. Relative inting height is a ratio that expresses the percent contribution of sitting height — ne length of the head, nech and trunk - to total stature (Lohman, Roche, and Mariveell 1988). In practice, this ratio is most often used as an indication of length differences between individuals or populations. The reason for this is due to the cephal-coundal gradient of growth, which means that during the years of growth the head and trunk are always closer to the legs begin to grow relatively faster than the head and trunk of the body.

and representing populations from many countries. The samples include people the relative sitting height data. Eveleth and Tanner fours on only a few of these (Europe), from Ibadan, Nigeria (Africa), Hong Kong (Asia), and of Australian longest legs followed, in order by Africans, Europeans, and Asians. Expressed quantitatively, "at a sitting height of 60 cm, for example, London boys have leg lengths averaging 43 cm. Ibadan boys 53 cm and Australian Aborigine boys 61 cm 390) we analysed a total \sim living on most of the major continents and islands of the world. When discussing samples, which they consider to be representative of four major geographic regions of the world. The 1976 edition of their book pres ats samples from London Aborigine origin (Australia). In proportion to sitting height, the Australians had the measured at different ages (Eveleth and Tanner 1976 p. 229). In the 1990 edition of their book they analyse rom 1976 (Australia). The (Africa) measured for the NHANES II study (a nationa wudy of health and nutrition data from Bergen (Europe), the People's Republic of China (Asia), "Afro-Americans" gth as found in 1976. 874 samples of relative sitting height of boys and girly 1990 analysis finds almost the same differences in leg i. By organising the samples in this way, Eveleth ar From the data found in Eveleth and Tanner (1976. in the United States), and the Australian Aborigines

of mankind coincide with 'sland chains. as is evident hers have assumed that the body proportion differences between geographic populations are explainable only in terms of a genetic or "racial" model. The population difference in body proportions is and legs in hot and humid regions and short appendates in cold regions. There is determination of body proportions are known and a planable genetic mechanism that usually considered to be an adaptation to regional clirt (cs, for example, long grup considerable evidence to support the correlation between climate and body proportions (Roberts 1953 is the classic study). However, no genes for the - 1971). Garn (1971, p. 17 d Tanner are employing might account for population differences in body shape has never been formulated geographic "racial" typology (Garn and Coon 1955, G-18) states that, "To a large extent the geographical ra-the major continents and...may also be spread over maj in the Pacific today." Over the past century, many rese-

We use guote marks when writing the word "race" because that term implies is biologically definable group of people. Definable biological distinctions between socalled "races" do not exist at the genotypic or phenotypic level (Bogin 1993, Lasker 1999). "Race" does have some value as a shorthand term to categorise people intogroups that differ in economic opportunities, social org, misation and resources, and political power. In the United States those people who are classified as "white" enjoy, on average, greater socio-economic opportunities and political power than those classified as "black." These differences have an impact on social resources that

lifferent guographic areas. These areas conform to the four major world regions Africa, Asia, Australian, Europe, Eveleth and Tanner (1990, p. 188) attribute the differences in relative sitting height and other body proportions to "racial differences." Indeed, all of the growth data presented in both editions of Worldwide races." These "races" are Europeans. Africans, Asian, Australian Aborigines and Pacific Islanders (including New Guineans and Maoris of New Zealand), Indo-Mediterraneans (includes Algeria, Egypt, Ethiopia, India, Iran, Israeli Kurds and and Mexican Mestizos. The geographic "racial" classification is reinforced in their work in that Eveleth and Tanner are more concerned with the putative geographic origin of the samples than with the location at which they were measured. For example, Black children measured in Tanzania and Black children measured in Washington, DC are considered to be "African race." Native Canadians (Indians of Canada), the Maya of Guatemala, and Chilean Indians are considered to be "Asian race." Any samples of children in the United States with light skin colour and The analysis presented by Eveleth and Tanner compares four samples from defined by many of those researchers using a "racial" typology to divide humanity --Yemenites. Pakistan, Saudi Arabia, Turkey, and Yugoslavian gypsies), and a final group of inter-racial crosses", such as Cuban mulattos, South African Coloureds, cariation in Human Growth are organised into categories based upon geographical claiming European origin are considered to be of the "European race."

2.1 Materials and methods of the re-analysis

We retain the geographical "race" scheme employed by Eveleth and Tanner in our reanalysis of their data on relative sitting height and we add several new variables. In all, we assigned an AGE, SEX, RACE, REGION, WORLD, SES, and SES x WORLD variable to each sample. The numeric values assigned to sub-samples within each variable are given in Table 1. These new variables are defined as follows. AGE is the chronological age of a sample. Whole years are used to define AGE, meaning that AGE 7 included all individuals between 7.00 and 7.99 years old and so on for all other ages. Any individuals age 20 or older were considered adults and were assigned the AGE score of 20. The SEX variable indicates the biological sex of an individual. that is, either male or female.

RACE is the geographical "race" categorisation as found in Eveleth and Tanner (1976, 1979). As stated above, this means that Tanzanians and fifth generation Blacks living in the United States are "Africans." REGION is the geographic location where each sample was measured regardless of "race" categorisation. This means that Blacks and Whites measured in the United States and Canada are coded as North American REGION, and any sample measured in Africa are African REGION. The RACE variable assesses variability in body proportions by sorting people into purported historical populations. The REGION variable provides an assessment of the effect of current geographic location on body proportions of a sample.

•

and Tanner. Most often, the authors of these papers describe their samples as "low SES," "middle SES," or "high SES." However, not all of the original papers included measures of SES for their sample. Also, we could not locate all of the original papers. Our assignment of a SES score to each sample is, therefore, a mixture of quantifiable information and qualitative assessment based on our best the SES information provided in each of the original publications cited by Eveleth makes the SES variable the most difficult to assign with accuracy. We tried to use estimate of the general socio-economic status of the sample.

and WORLD. We included this variable based on existing empirical research showing an interaction between SES and WORLD on human growth (e.g. Henneberg and Van Den Berg 1990, Bogin 1999). For example, low SES Maya children growing up in the United States, a first world nation, are significantly taller and heavier than low SES Maya children of the same ages growing up in their third The SES x WORLD variable is the multiplication product of the variables SES world homeland of Guatemala (Bogin and Loucky 1997).

Ridge regression is used when multicollinearity exists between the independent variables. A test for multicollinearity found that the variables WORLD and SES x WORLD were highly correlated with the other variables. Ridge regression reduces the effects of such high correlations by adjusting the regression model for more For analysis, each of these variables was entered into a ridge regression model. reliable beta coefficients.

2.2 Results

A summary of the regression analysis is presented in Table 2. We find that AGE explains 42% of the variance in relative sitting height of the 874 samples in the Eveleth and Tanner database. As is well known, relative leg length increases from variance. The SEX variable explains only 0.002% of the variance, which is not infancy to adulthood. The geographical RACE organisation of the samples explains 3.6% of the variance and SES variable accounts for an additional 1.0% of the total statistically significant. The other variables did not enter the regression model.

(lambda set at 0.10). R = 0.684, $R^2 = 0.465$. F(4, 869) = 191.03, p < 0.000. Standard et are 2.083 Table 2. Summary of the stepwise ridge regression model for relative sitting height

generally low SES. The sample was divided into four SES regions: 1) a region of intensive export agriculture. 2) a region of cattle for meat production, 3) a region of mixed agriculture and dairy herding, both for national consumption, and 4) a region of sub-istence agriculture. The authors also divided the sample into four ecological region-1) Pacific coastal plain, 2) Sierra Madre mountains. 3) Central Valleys, and 4) Central Plateau. Finally a demographic division was made between those women living in rural or urban areas. The authors found that 80% of the variance in stature in the sample was due to SES region and that 20% of the variance was due to ecological region. Almost all of the differences in stature within the sample were due to variation in growth of the leg. Women from the SES regions of export agriculture and the cattle raising area were the tallest. Women from the highland ecological regions were, generally, the shortest. Similar findings are reported for children and adults living in the Yucatan (Murguia et al. 1990, Dickinson et al. 1990). These Mexican studies indicate that even within a generally low SES population. life style differences exist and exert influence on body proportions.

3. RAPID CHANGE IN THE BODY PROPORTIONS OF MAYA CHILDREN

3.1 Materials and methods

Since 1992, we have studied the growth of samples of Maya children living in the United States (Bogin and Loucky 1997). These children are the offspring of Maya adults who immigrated from Guatemala to the United States, mostly from the late 1970s to the early 1990s. Some of the Maya children measured in our 1992 survey were born in Guatemala or Mexico and some were born in the United States. Our survey shows that the children of Maya immigrant parents are significantly talier than Maya children living in Guatemala (Bogin and Loucky 1997). We did not measure body proportions in that study, but we hypothesised that an increase in relative leg length accompanies the increase in stature. 1992

We measured the height, weight, and sitting height of 360 Maya children ages 6 to 12 years old, living in south central Los Angeles in February 1999 and in Indiantewn. Florida in March. 2000. With these data we computed the sitting height ratio. We compared these newer data with the data for height of the 1992 samples and with the data for height and sitting height ratios of a sample of Maya schoolchildren iving in rural Guatemala measured in 1998 (n = 1297). The Guatemalan data were A new study of the growth of Maya children in the United States began in 1999. kindly applied by Luís Rios of the Universidad Autónoma de Madrid.

3.2 Results

Mean values for height and sitting height ratio for each sample are shown in Figures and 3. Anthropometric reference data from the NHANES I and II surveys of the United States (Frisancho 1990) are used as a baseline for comparison in each graph. Analysis of variance (ANOVA) was used to evaluate differences between samples. measured in 1998 (Maya-Guati and the United States referen-

000

After adjusting for the effect of age and sex, our results show (Figure 2) that the Maya chalter of the 1999 and 2000 samples (abbreviated as "Maya-USA 2000") are significantly taller (Figure 1) than the Maya samples measured in 1992 (abbreviated as "Maya-USA 1992") and Maya children living in Guatemala (abbreviated as "Maya-Guat"). The Maya living in the USA also have smaller sitting height ratios than Maya living in Guatemala (Figure 3). All differences are significant at p < .01. A smaller sitting height ratio generally indicates a child with relatively longer legs. Compared with the NHANES references, all of Maya are shorter and have higher sitting height ratios, i.e. relatively shorter legs.

3.3 Discussion

Our findings add further support to the literature on developmental plasticity in body proportions. The results indicate that between 1992 and the present, there is a clear, and positive, trend in growth of Maya children living in United States. The reasons Maya in the USA have access to clean drinking water, health care, and education. The Maya children living in Indiantown, Florida participate in school breakfast and lunch programs. Nearly all of the Maya children have at least one parent with a wage-earning job. All of this provides the Maya in the United States with a higher standard of living than that found in Guatemala, as clean water, health care, education and wage paying employment often do not exist for Maya living in rural Guatemala. These health, economic, social, and nutritional changes are known to result in greater stature. Our findings support the hypothesis that the increase in stature is due mostly to relatively longer legs. We predict that the positive trend in height and sitting height ratio seen between 1992 and 2000 will continue for the Mava in the for this trend are likely due to improvements in the environment for growth. All United States. Eventually heights and body proportions should achieve values that approximate those for long-term residents of the United States.

4. CONCLUSION

In this article we have taken a critical look at the concept of genetic potential or genetic determination of human body proportions. We find that population differences in body proportions are influenced very little by genetic background, at least as imputed from geographic, ethnic, or "racial" categorisations. Our findings stand in sharp contrast to the opinion found in several of the most widely consulted books on human growth. In a more general sense, the whole concept of "genetic determination" in human growth is seriously flawed. That notion implies that the flow of information about how any human trait is developed, be it height, body fatness, personality, or intelligence, originates in the DNA and then unfolds into the phenotype. Within this scenario, one may allow for a greater or lesser amount of begins with the DNA and moves one way.

The roles of DNA in human development are much more complex, and often much less direct, than this. Genes do not directly cause growth and development. Rather, the many proteins that genes produce, which are mediated by the endocrine and neurological systems. regulate the expression of a genetically inherited pattern of

growth. The physical and social environment also mediate -i towth. In the case of the Prague study discussed in the introduction of this article it is important to note that the parents and children were fiving in the same how cholds and, therefore, shared a very similar environment. It is too simplistic, therefore, to ascribe the similarities in growth between parents and offspring to gene alone.

The interactions between genes, hormones, and the environment may flow in all directions. A marvellous example of the interaction of genes, proteins, and the endocrine system may be seen in the action of homeobox genes and Hox genes. The advances of molecular biology of the past two decades. The lameobox is sequence of 80 DNA base pairs that codes for a 60 amino acid segment of a protein. First sequences -- the same homeobox sequences are found in . ganisms as diverse as description and elucidation of homeobox and Hax genes is one of the most important discovered in the genome of the fruit fly. Drosophila, homeobox sequences are found in all eukaryote organisms so far examined. These highly conservative DNA hydra, nematodes, all arthropods (the group that includes in acts) and all chordates (the group that includes human beings) -- produce proving that regulate the expression of other genes, "...and control various aspects of morphogenesis and cell differentiation" (Mark *et al.* 1997, p. 421). *Hox* genes are protected of homeobox genes that encode transcription factors (Holland and Garcia-) ernàndez 1996), which NNA code to the RNA are proteins that initiate and regulate the conversion of the sequence that is used to make amino acid poly peptide chains.

te relative positions of body regions, for example the head, thorax and abdomen connisects, or the general greatest impact during the earliest stages of development. The proteins that 479). The DNA affected by homeobox proteins will, in turn, produce other proteins any effect. In placental mammals, the biochemical environment of the egg cell and, a nes seem to have their homeobox genes produce are needed to regulate the expression of other DNA to, "...sculpt the morphology of animal body plans and body "arts" (Carroll 1995, p. via a process called en segment of DNA le environment to have bit later in time, of the mother's womb and the placenta, placing a host of factors These "down stream" molecular zipping before they have any effect on a ground (McKnight 1991). These and other proteins need an approprim that mediate cellular differentiation, growth, and developme proteins do not act alone. Some of them must combir In multicellular animals, homeobox genes act to delimit body plan and limb morphology of vertebrates. Homeobox ${}_3$ needed for growth, including nutrients and hormones.

Throughout life, the endocrine system often provides the necessary biochemical Without these two hormones the genes that regulate growth of skeletal, muscle and adipose tissue will organs, and the body as whole. These nutrients influence growth via their effection the regulation of DNA expression, protein synthesis, and hermonal regulation (see Bogin 1999 for several additional examples). Because it is situated between the action of genes and the external environment, the endocrine system serves as a h spurt, for example. requires adequate amounts of two hormones. growth hormon: and testosterone (boys) The endocrine system us that affect human such as vitamin A or D and folate, can have major effects on the growth and development of tissues. or oestradiol (girls), to be secreted into the blood stream also responds to the influence of many environmental facdevelopment. Fluctioning asymmetry and human body proportions

Animal models are beginning to clarify the underlying biological processes of the development of budy proportions. Here we describe one experiment that manipulated the size of forewings and hindwings in the buckeye butterfly (*Precis coemia*). The authors of this study (Klingenberg and Nijhout 1998) were interested in the control of fluctuating asymmetry (FA), that is, departures from the anticipated or normal symmetry between the parts of growing organism. In bilateral organisms on ensure ty between the parts of growing organisms. In bilateral organisms on organisms with fore and hind limbs, wings, or other appendages it is possible to measure FA by comparing the size of the discussed as a potential indicator of measure FA by in being discussed as a potential indicator of measure FA by in both plants and greater developmental instability and greater environmental stress (Klingenberg and Nijhout 1998). The search for the factor- underlying FA, in both plants and animals, is an active area of developmental biology research.

Figure 4. Regression of dry weight per forewing (the average of left and right sides) on dry weight of the body for butterfiles from which one, both, or no hindwing imaginal discs had been removed (from Klingenberg and Nijhout 1998, p1136, with permission of the author) i : :

GENETICS OF BODY PROPORT.

controls. When only one treated side were heavier asymmetry and increase in weight of the growing forewings or legs diminished with greater physical distance between the removed imaginal disc and the remaining both hindwings, but had nts for the growth of the orewing are shown graphically in Figure 4. The authors note that the degree ${\rm ef}$ v and Nijhout (1998, p. he or both body sides of hindwing was removed, the forewing and hindleg on the than the untreated side." The results of these experim-In their experiments with the buttertlies, Klingen' 1135) "...removed the hindwing imaginal discs from caterpillars. Emerging butterflies were thus missing onheavier forewings, midlegs, and hindlegs than untreatu issue.

Imaginal discs are embryonic structures of inservating that provide the basic information and the tissue structures to form body segments in adult organisms. The developmental biology of imaginal discs are best work from the fruit fly *Drosophila*, where the limbs and eyes arise from divorte imaginal discs. The imaginal discs of *Drosophila* are epithelial sacs composed of a "...columnar cell monolayer covered by a squamous epithelium known as the peripodial membrane" (Gibson and Schubiger 2000). During the fly's developr on the peripodial membrane able to send biochemical information to the imaginal disc via microtubule connections. Experiments by Gibson and Schubiger (2000) demonstrate that biochemical communication between the peripodial $c \le and$ the imaginal disc influences the control of growth and pattern formation $c \le and$ the imaginal disc set and wing in the adult fly.

Based on the results of their experiments with bullerflies, Klingenberg and rotubules, exists between are consistent with the ompetition is a possible rongly indicate that the 'or a haemolymph-borne the work of Gibson and ransmit information and pate in the developmental resource, such as a nutrient or growth factor. Such -Nijhout (1998, p. 1135) concluded that. "Our finding hypothesis that the growing imaginal discs compete Schubiger which finds that a physical connection, via new the imaginal disc and the peripodial cells, which car mechanism for feedback interactions and may thus particontrol of asymmetry." This hypothesis is strengthened resources to the disc cells.
