

We thank members of the community for a thoughtful discussion regarding our recent publication, reported in doi: 10.1016/j.cell.2019.05.004; PMID: 31150625. In addition, we appreciate the broader comments on the gut microbiota, mouse models, and statistical analyses. We would like to address the following points raised during post-publication:

1. A number of reports, from many groups worldwide, have found differences in the human microbiome (from stool samples) between individuals with autism and typically developing populations (reviewed in PMID: 30251184, with >20 original articles). These studies in humans are unable to resolve the root cause of microbiome changes (potential examples include diet, genetics, etc.), or whether these observed differences have any biological relevance. The goal of our study is to take a next step in this line of existing research, by testing whether colonization of mice with microbiomes from individuals with autism can influence mouse behaviors, compared to controls (typically developing donors). These studies cannot be performed in people, but allow for a functional evaluation of the microbiome in mice, beyond simply reporting differences in microbial profiles. Our experiments do not, and cannot, conclude that the microbiota is causative in autism. In fact, we clearly state in the manuscript that our results do not demonstrate causality. Moreover, our work does not establish a new mouse model, which we have never claimed, but serves to test whether microbiota from ASD individuals can affect mouse behaviors.

2. It is our position that mice do not develop autism, but rather can be used to investigate mouse behaviors that are analogous to those of humans (PMID: 20559336, 27305922). Mouse models therefore enable testing of behaviors, classified by behavioral neuroscientists as being close to those behavioral domains in humans, in controlled systems. In our study, we tested outcomes that are regarded as similar to the main behavioral domains in autism, namely stereotypic/repetitive behavior and social interaction. While modeling complex behaviors in mice has limitations, this approach is a widely-accepted tool in behavioral neuroscience and has been used in hundreds of peer-reviewed publications.

3. Statistical analyses, part of Figure 1, specify linear mixed effects modeling of individual mice, nested within donor, and round of testing. Fixed effects included donor ASD diagnosis, mouse sex, and the interaction of these factors. You will note that we also ran models stratified by mouse sex, because DSI was only evident in male mice. Diagonal covariance matrices were specified so that mice sharing donors would be allowed to share variability while maintaining independence from other donors. Likewise, this was also used for testing Round. Because the number of donors was not large, more complex models specifying random effects did not converge and were not stable, and thus we decided to adhere to a parsimonious model to address our research question. We are providing the original SPSS output of the statistical analysis presented in Figures 1E – G for reference; the syntax use for analyses is included therein.

Thank you again for the constructive dialogue.

We present the original, unaltered output files of the statistical analysis used for our paper. This analysis was performed as part of a larger project, and any page breaks are due to analyses that were removed as they were never used in the paper. The analysis used to generate statistics for Figures 1E - G is shown in its entirety.
